Background

- V1 receptive field size scales linearly with eccentricity[3]

- How do spatial frequency preferences change across the visual map?
- Previous results show peak spatial frequency decrease with eccentricity, but actual numbers vary by two to three octaves!

- Variability perhaps due to inconsistent stimuli

Hypothesis

SF preferences scale with eccentricity / receptive field size

SF preferences constant across visual field

Experiment

- Showed 5 subjects 40 log-polar stimuli (8 phases each) from 4 classes with 10 different base frequencies in 12 runs
- For a given base frequency, all classes have same spatial frequency, but different orientations

Methods

- GLMdenoise[1] to define a (bootstrapped) response amplitude per voxel per stimulus
- Bayesian retinotopy[2] to define an eccentricity and angle for each voxel's population receptive field

Results

- Extract preferred period from tuning curves, then take median across bootstraps and average across subjects (weighted by precision), fit line (with intercept=0) as function of eccentricity

Trends are broadly similar across subjects, though two are **way** noisier

Conclusions & Future Directions

- V1 spatial frequency preferences scale as the inverse of eccentricity, at approximately the same rate as V1 receptive field size
- Subjects all show approximately this pattern, though data quality varies greatly
- Model response in each voxel as an anisotropic 2d Gaussian over ω_x and ω_y, allowing us to predict response to additional stimuli (intermediate log-polar stimuli and constant gratings)
- Investigate whether individual differences in noise are due to subjects falling asleep
- Investigate if spatial frequency preferences vary with population receptive field polar angle
